ABSTRACT

We used a coupled physical–biogeochemical model to investigate how the strong eddy activity typical of the Mozambique Channel affects biological production. A numerical experiment was carried out, in which mesoscale dynamics were suppressed by cancelling the nonlinear terms for horizontal momentum in the Naviers–Stokes equation. Mesoscale dynamics were found to be responsible for (1) increased offshore production in the Mozambique Channel as a result of net eddy-induced offshore transport of nutrient-rich coastal waters; (2) decreased shelf production along the central Mozambican and south-west Madagascar coast caused by a reduction in nutrient availability related to the net eddy-induced lateral transport of nutrients; (3) increased coastal production along the northern Mozambican coast caused by eddy-induced nutrient supply.

The model results also showed an intensification and shallowing of the subsurface production, related to increased upper layer nutrient concentrations caused by eddy activity.

In addition, by driving the detachment of the East Madagascar Current at the southern tip of the island, inertial processes intensify the southern Madagascar upwelling and causes offshore diffusion of the upwelled waters.

These results emphasize the complex role played by eddy activity and, more generally, inertial processes on marine ecosystems in this region.

1. Introduction

By supplying nutrient-rich waters to the near surface layer which is depleted in nutrients, mesoscale eddies are known to play a key role in the stimulation of biological production (McGillicuddy et al., 1998; Oschlies and Garçon, 1998; Williams and Follows, 1998; Lévy et al., 2001). This nutrient supply is primarily exercised through vertical pumping from subsurface nutrient-rich layers (McGillicuddy et al., 1998; Oschlies and Garçon, 1998; Lévy et al., 2001) and lateral transport from nutrient-rich waters to low nutrient environments (Williams and Follows, 1998). This conventional view of eddies stimulating biological production was recently found inadequate in eastern boundary upwelling systems (Lathuilière et al., 2010; Gruber et al., 2011). Using both observational and model simulated dynamics, Gruber et al. (2011) showed that eddy activity exerts a suppressive effect on coastal biological production in coastal upwelling systems.

This reduction in coastal production was related to the eddy-induced intensification of lateral transport of coastal productive waters toward offshore regions (Gruber et al., 2011). This came in support of a study by Lathuilière et al. (2010), in which using an idealized circulation model of a coastal upwelling, the authors found a reduction of coastal production due to mesoscale variability. This finding raises the question of whether a reducing effect of eddy stirring on coastal production could also occur in regions with much stronger eddy activity. The present study aims to investigate the impact of mesoscale eddies on biological production in the Mozam-
bique Channel, a region characterized by intense eddy activity, with a particular focus on the effect of eddy dynamics on coastal production.

The Mozambique Channel is a western boundary current system, where the eddy activity is among the strongest in the world (Chelton et al., 2007). The ocean circulation of the Mozambique Channel is dominated by large anticyclonic rings, which propagate southwest through the Channel (Saetre and Silva, 1984; Grundlingh, 1995; de Ruijter et al., 2002; Schouten et al., 2003; Halo et al., 2014). These eddies are often in strong interaction with the continental shelf and the coastal regions (de Ruijter et al., 2002; Ternon et al., 2014; José et al., 2014). These eddy-shelf interactions result in offshore entrainment of coastal productive waters (Quartly and Srokosz, 2003; José et al., 2014; Lebouorges-Dhaussy et al., 2014).

In this study, we used a coupled physical–biogeochemical model developed by José et al. (2014) to simulate realistically the dynamics of the Mozambique Channel. After validating the simulated dynamics against the observed data, we ran an idealized experiment in which we removed the terms responsible for the occurrence of eddies. This was performed by canceling the advection of momentum, all the other terms and parameters being kept strictly the same. Gruber et al. (2011) have used the same method for testing the role of eddies on biological production in the California Current System. As described by Gruber et al. (2011), the advantage of this method over the coarsening of the horizontal resolution is a better preservation of large scale Ekman and geostrophic circulations. By using the method in which the advection of momentum are cancelled, we investigate the effects of mesoscale dynamics on biological production without including other potential sources of differences.

By comparing the realistic simulation with the idealized experiment, we demonstrate that the role of eddy activity on coastal production is complex, with both reducing and increasing coastal production, depending on the location.

2. Material and methods

The physical–biogeochemical model configuration used for the Mozambique Channel consists of a hydrodynamic model ROMS (Regional Ocean Modelling System) coupled with a biogeochemical model PISCES (Pelagic Interaction Scheme for Carbon and Ecosystem Studies). This configuration is based on the ROMS_AGRIF two-way embedding procedure (Debreu et al., 2008, 2012) to nest a high resolution regional domain (child grid) within a larger scale domain (parent grid). ROMS is a split-explicit, free surface, terrain-following vertical coordinates ocean model, which solves the primitive equations of Navier Stokes in the presence of rotation (Schepetkin and McWilliams, 2005). PISCES is a biogeochemical model that simulates the first trophic levels of the marine ecosystem and the biogeochemical cycles of carbon and the main nutrients (Aumont and Bopp, 2006). The PISCES parameterizations are described in detail in Aumont and Bopp (2006). This model has 24 compartments, of which four are living pools composed of two phytoplankton size-classes (nanophytoplankton and diatoms) and two zooplankton size-classes (microzooplankton and mesozooplankton). It incorporates phytoplankton growth limitation by five external nutrients: nitrate, ammonium, phosphate, silicate and iron. The Mozambique Channel configuration, described in detail by José et al. (2014), consists of a parent domain at 1/2° horizontal resolution, covering the south-western Indian ocean, while the child grid domain at 1/6° resolution extends from 32° S to 1.5° S and from 28° E to 61° E. In this region characterized by a first baroclinic Rossby radius of deformation ranging from 50 to 100 km (Chelton et al., 1998), a resolution of 1/6° resolves most of the spectrum of mesoscale eddies. This is confirmed by the level of mean eddy kinetic energy in Fig. 1. The surface forcing fields consist of monthly climatologies presented by Penven et al. (2008) and atmospheric dust deposition from Fung and Tegen (1995). Due to the absence of reliable data on river nutrient discharges in this region, river inputs are not included in this configuration. Initial and boundary conditions for all the prognostic variables are derived from a monthly climatology of a NEMO/PISCES model simulation of the Indian Ocean (Koné et al., 2009). This realistic ROMS configuration is used as a reference and is referred to as REF.

To quantify the impact of mesoscale dynamics on biological production, we have performed an experiment in which the mesoscale dynamics were suppressed (NoADV). To do so, we have cancelled the nonlinear advection terms in the Navier–Stokes equations for horizontal momentum. The cancellation of advection of momentum can be seen as a linearization for a low Rossby number, if we suppose that the eddies have negligible upscaling effects on the large scale circulation. The absence of advection of momentum prevents the occurrence of coherent structures such as eddies and non linear cascades of energy (Yeung and Brasseur, 1991; Zhou, 1993; Eyink and Sreenivasan, 2006). This method is similar to the one described by Gruber et al. (2011) for their “non-eddy” simulation.

With the cancellation of these terms, we expect a suppression of eddies in the NoADV simulation, while the mean large scale circulation should be mostly preserved (since it follows linear Sverdrup dynamics).

Both simulations were run for a period of twenty climatological years, in which the model showed stable conditions after six years of simulation. Thus, the model outputs analyzed in this study were built by averaging, over the last ten years, the simulated fields of the high resolution child grid.

An extensive model–data comparison has been conducted using in situ climatologies and satellite products (José, 2014; José et al., 2014). It shows that the model is able to reproduce the mean state, seasonal cycle and eddy variability for physical and biogeochemical variables in the Mozambique Channel.

3. Results

3.1. Ocean circulation in the Mozambique Channel

The surface mean eddy kinetic energy (EKE), sea surface height (representing the surface circulation and surface elevation) and the mean sea surface currents from both simulations and AVISO altimetry products for the period 1993 to 2012 (produced by Ssalto/Duacs and distributed by Aviso, with support from Cnes —http://www.aviso.altimetry.fr/) are presented in Fig. 1. The simulated EKE from REF exhibits patterns consistent with AVISO altimetry (Fig. 1a,b), with values exceeding 1400 cm²·s⁻² in the central Mozambique Channel. By cancelling the advection of momentum in NoADV, EKE decreased to below 100 cm²·s⁻² in the Channel (Fig. 1c).

The modeled surface height and surface currents for early December of model year 20 show an absence of eddy structures in NoADV, while in REF, anticyclonic and cyclonic eddies are present in the Channel (Fig. 1d,e). This confirms that the advection of momentum succeeds in the removal of Mozambique Channel eddies. The remaining EKE in the northern part of the domain in NoADV could be related to Rossby waves propagating from the east, resulting in variations in the NMC (Schouten et al., 2003). The remain EKE further east could be related to waves generated on the Mascarene plateau (New et al., 2013).

The intensity of the observed and simulated geostrophic currents suggests that the REF simulation captures the strength of the surface currents of the south-western Indian ocean system, relevant to the circulation in the Mozambique Channel (Fig. 1f,g). However, the magnitude of the simulated North Madagascar current (NMC, around 100 cm·s⁻¹) is higher compared to AVISO altimetry (around 50 cm·s⁻¹), but is consistent with in situ observations presented by Schott and McCready (2001). The flow along the northern Mozambican Channel coast is consistent with the observed
Fig. 1. Sea surface physical dynamics of the south western Indian ocean. (a−c) eddy kinetic energy \(10^2 \times \text{cm}^2 \text{s}^{-2}\), (d,e) sea surface currents (arrows) overlaid on sea surface anomaly [cm] for early December of model year 20 and (f−h) sea surface height [contour every 10 cm] overlaid on the current intensity [cm \(\cdot \text{s}^{-1}\)]. Variables corresponding to AVISO observations (a,f), REF simulation (b,d,g) and NoADV experiment (c,e,h). Magenta lines in panel (e) show the location of the vertical sections displayed on Fig. 2.

field of Saetre (1985) and shows southward currents with intensity up to 75 cm \(\cdot \text{s}^{-1}\). These results emphasize the underestimation of the magnitude of the surface currents by AVISO altimetry products (Ternon et al., 2014). By comparing AVISO and the in situ measured surface circulation, Ternon et al. (2014) found an underestimation of about 30% in altimetry observations compared to ADCP measurements and of about 20% compared to drifters.

Cancelling the advection of momentum did not, in contrast, significantly alter the major patterns of the large scale circulation of this region (contours in Fig. 1h). Both REF (Fig. 1g) and NoADV (Fig. 1h) reproduce the observed large scale mean surface patterns, showing the South Equatorial Current (SEC) flowing westward and its bifurcation east of Madagascar (Schott and McCreary, 2001; Schott et al., 2002; Palastanga et al., 2006, 2007). The north-going branch of the SEC, the NMC, appears closer inshore and more intensified in NoADV than in REF and AVISO. Further west, the NMC splits into two branches: the East Africa Coastal Current EACC and the southward mean transport through the Mozambique Channel. Inside the Mozambique Channel, the mean local surface circulation is modified by the absence of mesoscale eddies. The flow through the Channel is predominantly southward and weaker in NoADV than in REF and AVISO. This weaker flow in NoADV illustrates the rectification effects of Mozambique Channel eddies on the mean circulation pattern of the Channel. In contrast to NoADV, the REF and AVISO surface circulations present a northward flow in the middle of the Channel, adjacent to a southward flow, consistent with the passage of anticyclonic Mozambique Channel rings.

The southward-going branch emanating from the split of the SEC, the East Madagascar Current (EMC), propagates along the east coast of Madagascar. South of Madagascar, the EMC hugs the shelf break in NoADV (Fig. 1h) while in REF (Fig. 1g) and AVISO (Fig. 1f) it detaches from the topography at the southern tip of Madagascar. Surprisingly, there is still a retroflecting loop in the mean EMC and the South Indian Counter Current (SICC) is present, despite the absence of advection of momentum in NoADV. However, this loop occurs earlier in comparison to what is simulated in REF. This retroflection
The suppression of mesoscale dynamics in NoADV reveals significant alterations in the current intensity and structure of the Mozambique Channel circulation related to eddy activity (Fig. 1g,h). North of Madagascar, the NMC appears intensified and confined inshore in NoADV (Fig. 1h). Conversely, the following westward flow toward the African coast appears weaker in this simulation. In REF, the core of the NMC appears slightly detached from the shelf in the northern tip of Madagascar, allowing the generation of an eastward circulation inshore (around 12°S and 49°E, Fig. 1g, Fig. 2a,b). This inshore eastward circulation has been related to the friction on the inshore edge was previously related to the eddy activity generated in the southern tip of Madagascar by the detachment of the EMC from the coast (Grundlingh et al., 1991). The NoADV experiment also highlights the role of south Madagascar dipole eddies (de Ruijter et al., 2004) on the northward intrusion of water from the south into the Mozambique Channel. REF and AVISO show a cyclonic loop in the south east part of the Channel which is not represented in NoADV, where the flow is dominantly westward towards the African coast. This cyclonic loop could be related to a rectification effect due to the presence of cyclonic eddies generated south of Madagascar.

Fig. 2. Vertical structure of the mean velocity [cm s⁻¹]. (a,b) Zonal velocity (U) at the northern tip of Madagascar, around 49°E. (c,d) Meridional velocity (V) at the northern border of the Mozambique Channel, around 12°S. (e,f) Meridional velocity (V) at the narrowest part of the Mozambique Channel, around 17°S. (g,h) Zonal velocity (U) at the southern tip of Madagascar, 45°E. Model results corresponding to REF (left panels) and NoADV (right panels). The locations of the sections are presented on Fig. 1e.
of the NMC, which generates anticyclonic eddies that propagate into the Mozambique Channel (Backeberg and Reason, 2010). Reaching the northern Mozambique Channel, the anticyclonic eddies intensify and structure the flow through the Channel, with a southward flow along the western part and a northward flow along the eastern part of the Channel (Fig. 1g,h and 2c,d). This anticyclonic mean recirculation characteristic of the northern part of the Mozambique Channel is simulated in REF (Fig. 1g) but is not present in NoADV (Fig. 1h). This supports the findings of Collins et al. (2014), who related this recirculation to Mozambique Channel eddies. At the narrowest section of the Channel, around 17°S, the southward flow along the African coast is extended offshore and is surface intensified in REF (Fig. 2e,f), in agreement with in situ observed patterns (Ullgren et al., 2012). At the eastern Madagascar coast, the removal of mesoscale dynamics in NoADV did not affect the EMC (Fig. 1g,h). Downstream, at the southern tip of the island, the EMC appears attached to the coast, intensifying the coastal current (Fig. 1g,h and Fig. 2g,h). In contrast to NoADV, the detachment of the EMC from the shelf break in the REF allows an eastward flow onshore (Fig. 2g,h), triggering the formation of dipole eddies south of Madagascar (Fig. 2g,h, de Ruijter et al. (2004); Siedler et al. (2009)).

The impact of eddy activity in the Mozambique Channel is also evident from surface temperature and salinity (Fig. 3). In the northern part of the Mozambique Channel, the surface waters are slightly colder and fresher in NoADV (Fig. 3b,e). These changes seem to be related to the absence of the anticyclonic recirculation in NoADV. With the anticyclonic recirculation in REF, warmer waters on the central and northeastern side of the Mozambique Channel are diffused through the northern basin by the northward current present in the eastern Channel, increasing surface temperature (Fig. 3a–c). A similar pattern is observed for salinity (Fig. 3d–f). Similarly, saltier waters from the south are transported northward by the equatorward jet of the anticyclonic recirculation and are mixed with fresher surface water from the north-east, increasing salinity. Further south inside the Channel, the warm and fresh Tropical Surface Water (TSW), which propagates southward as a western boundary current, is closer to the shelf in NoADV. In this case, a sharp density front separates the warmer and fresher water along the western boundary from the colder and saltier water offshore. With the presence of Mozambique Channel eddies, water mass properties are mixed and the horizontal density gradient is reduced. This way, temperature is increased and salt content is reduced along the coast. Offshore, eddy turbulent diffusion induces an increase in temperature and a decrease in salinity. South of Madagascar, detachment of the EMC from the coast in REF transports the warmer and fresher TSW offshore. In addition, the cyclonic loop observed along the west Channel in REF brings southward warm and fresher waters from the central Mozambique Channel. Changes in water density induce changes in the mixed layer depth (MLD). In the northern Channel, the MLD is deeper in the west basin in REF. This suggests that heat and salt redistribution by the Mozambique Channel eddies deepen the MLD in the west side of the basin. Further south, the MLD is deeper in REF compared to NoADV. An exception is observed offshore, coinciding with the region of horizontal density gradient in NoADV. This suggests that the mixing induced by eddy activity in this region deepens the MLD.

3.2. Plankton and nutrient dynamics

The seasonal cycles of sea surface chlorophyll for both SeaWiFS remote sensing observations and REF are presented in Fig. 4. The simulated chlorophyll concentrations follow the variability of the observations. They show lower concentrations during austral summer (Fig. 4a,c) and higher concentrations during austral winter (Fig. 4b,d). This variability is related to seasonal changes in the upper
layer nutrient availability driven by variations of the mixed layer (Machu et al., 2005). In austral winter, surface cooling generates a deeper mixing, bringing upward deep nutrient-rich waters, which stimulates plankton production. In the Somali upwelling region (north of 6°S), high chlorophyll concentrations are more extensive during austral winter. In the subtropical gyre (i.e. offshore of Madagascar), chlorophyll concentrations are low in the model, in line with SeaWiFS observations. Although the model is able to reproduce the seasonal variability of the chlorophyll concentration, it fails to reproduce the higher concentrations along the coast, as well as the phytoplankton plume which is noticeable south-east of Madagascar in austral summer (Longhurst, 2001). The weak production along the coast could be related to the absence of a sediment compartment as well as river nutrient discharges in the model simulation. Both resuspension from sediments as well as river discharges enrich the coastal waters with nutrients, enhancing coastal productivity (Lohrenz et al., 1997; Johnson et al., 1999; Booth et al., 2000). The seasonal phytoplankton plume south-east of Madagascar has been recently related to nitrogen fixers (Srokosz and Quartly, 2013), which are not explicitly accounted for in the phytoplankton formulation used in the model.

The effect of mesoscale dynamics on plankton production is summarized in the annual mean primary production presented in Fig. 5. In NoADV, the productivity is more localized and confined to coastal regions of the Channel (Fig. 5b). In the presence of eddies in REF, coastal productive waters are diffused further offshore (Fig. 5a). The differences in primary production calculated as REF−NoADV are positive along the north coast of Mozambique (between 16°S and 10°S), the central west coast (between 21°S and 17°S) and at the southern tip of Madagascar (Fig. 5c). This is in contrast to reduced primary production in REF along the central Mozambican coast (between 25°S and 17°S) and south west of Madagascar (between 26°S and 23°S, Fig. 5c). Offshore in the Mozambique Channel, patterns are more homogeneous with generally increased surface primary production in the simulation with eddies. The vertical structure of primary production shows deeper and weaker subsurface maxima in NoADV (Fig. 5c). The shallower subsurface maxima in REF suggests an increase of upper layer nutrients induced by eddy dynamics (Fig. 5d).

To interpret these patterns, we examined the changes in nitrate (Fig. 6a–c), which has been suggested to be the limiting factor for phytoplankton production in the Mozambique Channel (Koné et al., 2009). In the northern Mozambique Channel (between 12–17°S), REF displays reduced surface nitrate concentrations compared to NoADV. This reduced surface nitrate concentration is in contrast to the patterns of productivity presented in Fig. 5c. Phytoplankton growth limitation by nitrate however, follows the production pattern (Fig. 6d–f). It shows that phytoplankton cells are less limited by nitrate in the west side of the basin compared to the east side in REF (Fig. 6d). The eddy-driven nitrate transport show a relation with the enhanced production in the west and reduced production in the east side of the basin (Fig. 7a,b). It shows elevated nitrate supply from the north-western side of the basin in REF (Fig. 7a), coinciding with the Mozambique Channel eddies main pathway (Halo et al., 2014). In the east side, the eddy-driven nitrate transport is weak and mainly northward. This northward transport is linked to the anticyclonic
eddy characteristic of the northern Channel (Collins et al., 2014), which brings less productive waters from the central Channel. In NoADV, there is a strong southward transport of nitrate in the northeast side of the basin (Fig. 7b), which explains the enhanced plankton production in Fig. 5c.

Considering now the central Mozambique Channel, the reduction in coastal nitrate south of 17°S (Fig. 6a) is directly related to lateral transport driven by the mesoscale activity (Fig. 7c–d). Eddy dynamics appear to intensify the offshore transport of shelf waters. This offshore transport reduces the nitrate availability in the shelf. In consequence, coastal phytoplankton growth is strongly limited by nitrate (Fig. 6d,e). Further, the eddy-induced lateral nitrate transport increases the offshore nutrient availability, stimulating offshore plankton production, but it is also associated with a reduction in coastal plankton production. These results are in agreement with Gruber et al. (2011) for the California upwelling system, where the authors found a reduction in coastal production caused by eddies.

Another remarkable change associated with advection of momentum is observed on the southern Madagascar shelf. South of Madagascar, the advection of momentum causes a detachment of the EMC from the shelf around 45°E (Fig. 1g). A current driven upwelling is associated with the divergence caused by the detachment at the southern tip of Madagascar (Machu et al., 2002). With the cancellation of advection of momentum (i.e. inertia) in NoADV, the EMC hugs the shelf break (Fig. 1h). The coastal upwelling is reduced (Fig. 7f). This can be seen for both primary production and nitrate south of Madagascar (Figs. 5b and 6b). In REF, the upwelling along the southern Madagascar coast is intense (Fig. 7e). Even though there is relatively strong upwelling off the south-west coast (between 25°S and 21°S, Fig. 7e,f), the detachment of the EMC caused a reduction in surface nitrate availability and phytoplankton production. In NoADV, the EMC follows the topography and advects nutrients onto the southwestern shelf of Madagascar resulting here in elevated new production when compared to REF.

In the central Mozambique Channel at 20°S, the presence of eddies changes the vertical structure of nitrate concentrations (Fig. 8ac). The eddy-induced lateral as well as upward transport of nitrate-rich deep waters (Fig. 8d) increases the upper layer nutrient concentrations and shoals the nutricline (Fig. 8a). Thus, phytoplankton growth is enhanced offshore by eddy activity (Fig. 5d–f). The increase of upper layer nutrients and primary production, as well as the favorable light conditions, results in an intensification and shoaling of the subsurface production (Fig. 5d–f). The auto-shading effect (reduction of deep penetration of light due to increased surface production) is also intensified. This can be seen from the vertical distribution of photosynthetically available radiation (PAR, Fig. 8f–h). The PAR is more attenuated in REF (Fig. 8f) than in NoADV (Fig. 8g) simulation. This auto-shading effect reduces phytoplankton production below the subsurface maximum (Fig. 5d–f).
4. Discussion

The aim of this study is to understand the role of mesoscale dynamics on the phytoplankton production in the Mozambique Channel, known for its strong eddy activity. We approached this task by implementing an idealized experiment in which the processes responsible for small scale generation are removed from the momentum equations. Both mean patterns and turbulent fluxes of this experiment are compared to an eddy-resolving realistic simulation. The cancellation of the non-linear terms did not affect the mean large scale circulation outside the Mozambique Channel (Fig. 1g,h). In the Channel, the mean circulation appear strongly modified by mesoscale dynamics, emphasizing the strong role played by eddy activity on the flow of the Mozambique Channel (Grundlingh, 1995; de Ruijter et al., 2002; Schouten et al., 2003). To the north, the results suggest that the anticyclonic recirculation characteristic of this region (Collins et al., 2014) shape the circulation patterns, by inducing a northward flow on the east side of the basin. This northward flow allows a northward transport of warmer and saltier waters from the central Channel (Fig. 3). These waters are mixed with the relatively cooler and fresher TSW brought into the Channel by the SEC (Schott and McCreary, 2001). Further south, the TSW are diffused offshore by the eddy stirring, reducing the northward propagation of cold southern waters. During this process, waters inshore got saltier and colder while waters offshore got fresher and warmer (Fig. 3).

The changes in the circulation and water mass properties lead to changes in the phytoplankton productivity. It came into view that the eddies in the Mozambique Channel could induce both a reduction and an increase of coastal production (Fig. 5a,b). The reduction of coastal production (which occurs in the central-west and south-east Mozambique Channel) is related to the eddy-induced off-shelf transport of coastal-productive waters, which reduces the coastal nutrient (Fig. 7c,d). With limited nutrients, the phytoplankton growth is reduced due to nutrient-stress (Fig. 6d,e), thus the productivity (Fig. 5c). A similar relationship has been described by Gruber et al. (2011) and Lathuilière et al. (2010) in the eastern tropical upwelling systems. The increased coastal production (which occurs in the northern Channel, Fig. 5a) is related to the eddy-induced nutrient injection into the MLD (Fig. 7a,b), as they intensify the southward flow through the Channel (Fig. 2c,d). Vertically, the eddy-induced upward transport of nutrient-rich deep waters (Fig. 8d) combined with eddy-induced lateral transport (Fig. 7a,c) increases the upper layer nutrient concentration (Fig. 8a). This is in agreement with the study by Oschlies and Garçon (1998), in which they found about one-third of the total flux of nitrate into the euphotic zone related to eddy activity.

5. Conclusions

It has been shown that eddy activity exerts a suppressive effect on coastal production in eastern boundary upwelling systems, by...
intensifying the lateral transport of nutrient-rich coastal waters (Lathuilière et al., 2010; Gruber et al., 2011). Gruber et al. (2011) have subsequently suggested that a similar effect might occur in other regions characterized by strong eddy activity. Our study on the Mozambique Channel, a region strongly dominated by eddy activity, showed heterogeneous and complex biological responses to eddy activity, with different processes involved in the induced changes. In this region, the mesoscale dynamics have both suppressive, as documented in eastern boundary systems by Gruber et al. (2011), and enhancing effects close to the shore. The suppressive effect was related to eddy-induced offshore transport of coastal nutrients combined with a reduction in nutrient injection from the lateral boundaries.

The enhancing effect was linked to the intensification of the southward transport of nutrient-rich waters throughout the northern boundary of the Mozambique Channel. On this basis, it is evident that the role of small-scale dynamics in the marine ecosystem is complex. Their effects on biological production are diverse. This complexity is strongly dependent on the circulation patterns at regional scales, which override the applicability of general schemes. Furthermore, this study emphasizes the need for a good representation of regional circulation patterns in global scale physical
models to better understand and predict future changes in ocean biogeochemical dynamics.
